ABSTRACT • Objectives: To evaluate the surgical approaches and prognosis of thyroid carcinomas invading the adjacent structures. Methods: The medical records of 197 patients with a pathology diagnosis of thyroid cancer were retrospectively reviewed. Results: Seventeen patients (9\%) with thyroid carcinoma invading surrounding structures were included. Patients were initially divided into two groups on the basis of tumor histology: papillary (Group A) and nonpapillary (Group B). Then patients were divided into three groups: Group 1: patients who underwent total thyroidectomy • Group 2: patients who underwent total thyroidectomy with shaving resection • Group 3: patients who underwent total thyroidectomy with extensive surgery. All patients who didn’t survive were more than 45 years old. The survival rate was statistically better in group A compared to group B (92\% versus 20\%). The survival rate decreased from Group 1 through Group 3, without reaching statistical significance. Conclusions: Age and histologic type are important in determining the prognosis of locally invading thyroid cancer. Keywords: thyroid cancer; invasion; age; surgery; prognosis

INTRODUCTION

Extracapsular spread is seen in approximately 5 to 15\% of cases of well-differentiated thyroid carcinoma. The predominant pathology leading to invasive spread is papillary thyroid carcinoma. Locally advanced thyroid cancer is secondary to direct primary tumor extension or extracapsular extension of involved lymph nodes [1-15]. Patients with extrathyroid extension have an increased incidence of local recurrence, regional spread, and distant metastasis.

The most common structures involved by extrathyroid extension in the central compartment are strap muscles, recurrent laryngeal nerve (RLN), trachea, laryngeal framework, esophagus, and pharyngeal constrictors. Structures in the lateral neck compartment that can be involved include the carotid artery, internal jugular vein, vagus nerve, spinal accessory nerve, and phrenic nerve [1,16-20].

Surgical resection is the primary treatment for patients with locally aggressive thyroid cancer. The principles of surgical management of locally advanced thyroid cancer are the following: (1) removal of all gross tumor, (2) preservation of functioning structures, (3) preservation of vital structures, and (4) use of adjuvant therapies. Some controversies still persist between authors advocating conservative surgical management since they did not find any improved local control and survival with the aggressive approach of invasive well differentiated thyroid carcinoma, and those favoring aggressive surgical approach over shave resection, reporting better local control and survival with extensive surgery [20-26].

The aim of this study was to review our experience in the surgical management of locally invading non-anaplastic thyroid cancers.

METHODS

Data retrieval
We retrospectively reviewed the medical records of all patients with a diagnosis of thyroid cancer treated at Hôtel-Dieu de France Hospital, Lebanon, from 1997 through 2007. These patients were identified using the results of their postoperative pathology specimens.

A total of 197 cases were included. Of the 197 samples, 17 (9%) patients were identified having invasion of at least one adjacent structure. The 17 patients were divided initially into 2 groups according to the presence or absence of papillary carcinoma (as per postoperative pathology results): Group A consisted of 12 patients with papillary carcinoma and Group B consisted of the remaining 5 patients with nonpapillary carcinomas. Then these 17 patients were divided again into 3 groups according to the type of surgery performed:

- Group 1: Patients who underwent total thyroidectomy or tumor ablation with no shaving or extensive resection.
- Group 2: Patients who underwent total thyroidectomy or tumor ablation with “shaving” resection.
- Group 3: Patients who underwent total thyroidectomy or tumor ablation with extensive surgery.

Inclusion & exclusion criteria
All the relevant clinical variables were analyzed including clinical presentation, pre- and postoperative tumor histology, prior medical or surgical history of thyroid disease. All patients with locally invasive primary or recurrent nonanaplastic thyroid carcinomas with or without distant metastases, who were treated at our department between 1997 and 2007 were included. Patients who were preoperatively diagnosed with anaplastic thyroid carcinoma on pathology were excluded.

Invasion was assessed either preoperatively clinically, radiologically and macroscopically (by laryngoscopy) or postoperatively by pathologic examination.

Surgical management
Preoperative ultrasound and fine-needle aspiration were done on all patients. Tumor extension was assessed preoperatively either by a computed tomography (CT) (Fig. 1) or by a magnetic resonance imaging (MRI) scan. Furthermore, all patients underwent a preoperative direct laryngoscopy. All surgeries were done under general anesthesia using horizontal cervical incision. Only one sternotomy was necessary for mediastinal lymph node dissection.

The type of resection was chosen in the operating room depending on either the presence of macroscopic intraoperative findings of invasion of adjacent structures or on the result of the frozen section. The thyroidectomies were all performed in a similar fashion with careful dissection attempting to identify and preserve the important adjacent structures such as the parathyroid glands with their vascular supply, as well as the recurrent laryngeal nerves. Inadvertently removed or unequivocally devascularized parathyroid glands were removed routinely for immediate autotransplantation.

Statistical analysis
All the qualitative data were analyzed using the chi-square statistic, corrected by the Fischer’s exact test when appropriate. Quantitative data are presented as mean ± standard deviation. Qualitative data are reported as proportions.

Survival curves were built using the Kaplan-Meier method and the survival rates were compared using the log-rank test. All statistical tests were two-sided. A p value less then 0.05 was considered significant. All statistical computations were performed using the SPSS® software (SPSS, Inc., Chicago, Ill.).

RESULTS
Seventeen patients with a preoperative diagnosis of nonanaplastic thyroid cancer with invasion of at least one adjacent structure satisfying inclusion/exclusion criteria were included in the study. The series included 12 women (71%) and 5 men (29%). The mean age at diagnosis was 53 years (extreme: 15-82 years). The symptoms of upper aerodigestive tract invasion were hemoptysis, stridor, hoarseness, dysphagia and aspiration. Only one patient had distant metastasis at the time of diagnosis.

The most common sites of involvement were the overlying striated muscles (83%), recurrent laryngeal nerves (31%), larynx (35%), trachea (29%) followed by esophagus (17%). The initial staging of the patients was T3-N0-M0, T3-N1-M0, T4a-N0-M0, T4a-N1-M0, T4a-N0-M1.

Total thyroidectomy was the surgical procedure performed on all our patients except on those who had recurrent disease following initial resection and who then underwent resection of their recurrent cancer.

Two patients had recurrent disease following thyroid...
resection for noninvasive carcinoma; one case of follicular carcinoma which was treated at first with right lobectomy and then with total thyroidectomy, and one case of medullary carcinoma which was treated five months earlier with total thyroidectomy with bilateral lymph node dissection. These two patients were not operated on in our institution.

Lymph node dissection of the central compartment (level VI) and of the ipsilateral jugulocarotid chains (levels III and IV) was performed on all patients treated with total thyroidectomy. Two patients underwent bilateral lymph node dissection of the jugulocarotid chains because of the involvement of both lobes of the thyroid gland by the cancer. Palpable lymph nodes or lymph nodes that were found highly suspicious for metastasis on intraoperative findings outside the jugulocarotid chains were also dissected. Thus a modified lymph node dissection was achieved in four patients.

Local resection of all macroscopic invaded structures was performed on all patients. Thus, the extension of local resection of the tumor depended on the macroscopic extension seen intraoperatively. When the tumor was adhering to either laryngo-trachea or esophagus without signs of invasion, a “shaving” resection was performed. When the trachea, the esophagus or the larynx were invaded by the tumor, partial resection of the invaded structure was performed. This is what we call extensive surgery or extensive resection.

Postoperatively, oral L-thyroxine and adjuvant radioactive iodide were given to all patients and 15 patients respectively. During follow-up, five patients died and all were more than 45 years old. None of the patients underwent postoperative external radiation therapy.

### Comparison of groups A and B

On final pathology, 12 patients had papillary carcinomas (Group A) of the thyroid (70%), 2 patients had medullary carcinomas (12%), one patient had follicular carcinoma (6%) and 2 patients had follicular and undifferentiated thyroid carcinomas (12%) (Group B).

Table I compares invasion symptoms, type of surgery, invaded structures and recurrence rates between the groups A and B. In group A, 4 patients had hoarseness (33%), 3 patients had dysphagia (25%), 2 patients had aspiration (17%), one patient had hemoptysis (8%) and one had stridor (8%). In group B, 2 patients had hoarseness (40%), one had stridor (20%), one had dysphagia (20%), and none had aspiration or hemoptysis (0%). Invasion symptoms of adjacent structures were equally distributed in the two groups ($p = 0.56$).

The striated muscles were invaded in 9 patients (75%) in group A and in all patients (100%) in group B. Four patients in group A (36%) and one patient in group B (20%) had recurrent nerve invasion. Recurrent nerve was sacrificed in 3 cases. Two have had surgical resection of papillary thyroid carcinomas with microscopic residual tumor tissue left around the recurrent laryngeal nerve to preserve it (provided that this residual tissue will be controlled by adjuvant 131I). The larynx was invaded in 4 patients in group A (33%) and in 2 patients in group B (40%). Four patients in group A (33%) and one patient in group B (20%) had invasion of the trachea. The esophagus was invaded in one patient in group A (8%) and in 2 patients in group B (40%).

Simple thyroidectomy was performed on 3 patients in group A (25%). Four patients in group A (33%) and 3 patients in group B (60%) had undergone shaving tech-

nique. Extensive surgery (n = 7) (wedge resection of the trachea n = 2, partial laryngectomy n = 3, and resection-anastomosis of the trachea n = 1) was performed on 5 patients (42%) in group A and 2 patients (40%) in group B. Concerning the type of surgery performed, no statistically significant difference was noted for simple thyroidectomy in the group of patients with papillary cancer (Group A) when compared to the group of patients with nonpapillary cancer (Group B) where simple thyroidectomy was not sufficient (0). However, there was no statistically significant difference (p = 0.686) regarding extensive surgery between the two groups which means that extensive surgery was performed with equal frequency in the group of patients with papillary cancer and in the group of patients with nonpapillary cancer.

During the follow-up (0-146 months) of all patients having papillary carcinoma (Group A), one patient died from liver and lungs metastasis at 11 months following surgical treatment. The 5-year survival rate in Group A was 92%. Conversely, of the 5 patients in Group B, only one patient (20%) survived the 5-year follow-up. The major etiology of death in this group was the cancer itself, either via recurrent disease with distant metastases (2 patients), follicular cancer with undifferentiated component (1 patient), medullary carcinoma (1 patient) or fatal local recurrence of a follicular carcinoma without distant metastases (1 patient). One patient died due to insufficient surgical control of the undifferentiated component.

The survival curves of groups A and B are shown in Fig. 2, showing a statistical difference in survival favoring the group A (p = 0.01). Recurrence was seen in 3 patients in Group A (25%) and in 3 patients in Group B (60%). An observed difference in the recurrence rate was noted between Group A and Group B without reaching statistical significance.

*p < 0.05 is significative
and 3 is shown in Table II. No statistically significant differences were found between the 3 groups. However, these symptoms were more frequently encountered in those patients having had extensive surgery (80%) compared to patients who have had “shaving” or simple thyroidectomy.

The 5-year survival rate in the non extensive surgery group was 100%. In fact, 2 of the 7 patients died from local recurrence and distant metastases following initial “shaving”. All the patients who underwent simple thyroidectomy and 5 of the 7 patients who underwent “shaving” resection survived till the end of the study (survival rates at 5 years were 100% and 72% respectively). The 5-year survival rate in group 3 was 57%. Three of the 7 patients died; 2 of them died as a consequence of the undifferentiated component of their follicular cancer that was locally very aggressive and had locally recurred.

The survival curves for the extensive and non extensive surgery groups (Fig. 3) were not statistically divergent ($p = 0.886$). The postoperative recurrence rates differed between the simple thyroidectomy (0%) and the extensive surgery cases (57%), without reaching statistical significance ($p = 0.08$).

**DISCUSSION**

There was a statistically significant difference in the survival rates between patients with papillary thyroid carcinoma (Group A) and those with nonpapillary cancer (Group B) in our series (92% versus 20%; $p = 0.011$). In fact, this was noted by Ballantyne [27] who reported that the survival rates were low for patients who had tumors other than papillary or papillary and follicular carcinomas. Bayles et al. [18] compared survival on basis of the histologic type of thyroid cancer (differentiated versus undifferentiated) and reported a better survival in the well-differentiated group.

Our results did not show a statistically significant difference in survival between extensive surgery and shave excision. Thus, they do not show an advantage of aggressive treatment over conservative treatment on the survival rates. Moreover, the survival rates were better in the non extensive surgery group (without reaching statistical significance). Survival rates at 5 years in our series were 100% in Group 1, 72% and 57% in Groups 2 and 3 respectively. All patients who didn’t survive after the procedure were more than 45 years old. In some retrospective studies [1,5,19,20,25], laryngotracheal invasion was noted to be an independent prognostic factor for survival. Shaving is acceptable if there is cartilage invasion but no direct intraluminal involvement [16-25]. This approach has been shown in many studies to be as effective in loco-regional control and survival as complete resection, without the morbidity that affects swallowing, speech, and voice. Residual microscopic disease can be effectively controlled with adjuvant radiiodine ablation or external radiotherapy [1,5]. Shave excision is not appropriate in cases of direct intraluminal invasion, which can lead to death. Complete resection is necessary in these cases. When all gross tumor was removed from the primary site, shave excision and complete resection techniques had similar survival rates. Some authors proposed and advocated shave resection for tumors with minimal invasion; for patients with gross intraluminal spread, techniques enabling complete resection of tumor were advocated [11-25]. In a systematic review, Kim et al. [5] reported varying survival rates for the two groups: 55% to 100% in the “shaving” group and 38% to 100% in the resection group.

The rates of recurrences were very similar between the shaving and laryngotracheal resection groups (15% to 28% for shaving and 7% to 39% for resection) [16-35]. In our series, recurrence rates were higher in patients treated with extensive resection than in patients treated with conservative approach (0% in Group 1, 29% in Group 2 and

![Figure 3. Survival curves of patients with invasive WDTC undergoing extensive versus nonextensive surgery](image-url)
57% in Group 3). Of note, patients treated with extensive resection had a deeper invasion of the surrounding structures, but this difference was not statistically significant. Thus, in the present investigation even the recurrence rates were not different from previously reported values regarding the practice of “shaving” technique.

The treatment of the recurrent laryngeal nerve invasion generates considerable controversy.

Appropriate preoperative evaluation of the vocal cords is imperative. If the recurrent laryngeal nerve is paralyzed preoperatively, it obviously needs to be sacrificed. If the nerve is functioning, however, the decision to sacrifice the nerve becomes difficult. If preservation of the nerve requires leaving gross tumor behind, then the nerve should be sacrificed. Before one recurrent laryngeal nerve is sacrificed, however, it is very important to make sure that the opposite nerve is not directly involved with the tumor and that it can be preserved. If preservation of the nerve requires leaving microscopic disease, then the nerve should be spared. Leaving microscopic disease on the recurrent laryngeal nerve does not lead to decreased survival or increased recurrence, in comparison with resection of the nerve [1,2,19,20]. Patients with residual microscopic disease should have postoperative radioiodine ablation and possibly external radiotherapy. For some authors, no survival benefit was realized with nerve sacrifice [19,20].

Appropriate preoperative imaging with CT or MRI, cervical ultrasound, and bronchoscopy is also very essential [1,12,15]. Invasion of the esophagus and pharynx is usually confined to the muscularis layer, without extension into the submucosa or mucosa. Invasion of the muscularis layer often leads to compressive dysphagia symptoms. Excision of the muscularis layer can be performed to obtain negative margins. With full-thickness or circumferential involvement of the cervical esophagus, a segmental resection is necessary.

The role of therapeutic neck dissection in the setting of thyroid carcinoma, typically including levels II through V, is accepted when clinical or radiographic evidence of regional metastasis exists. Elective lateral neck dissection beyond central compartment dissection is somewhat controversial. Some authors have advocated bilateral modified radical neck dissections at the time of thyroidectomy in patients with invasive disease because of the risk of nodal recurrence and the impact it may have on distant metastasis and survival [36-38].

Adjuvant treatment after complete resection with L-thyroxine suppression and radioactive iodine ablation are considered the treatment of choice for invasive thyroid carcinoma. In cases where tumors are not radioiodine avid and/or the procedure required to obtain complete removal is unacceptable, external radiotherapy can be effective in stabilizing locoregional disease with reduction in thyroglobulin levels in some cases [1,5,39-41]. Some authors routinely using intensity modulated radiation therapy (IMRT) in these patients to offer an effective radiation dose to the thyroid gland and avoid spinal cord injury. Several chemotherapeutic agents have been studied in patients with locally advanced thyroid cancer, but no significant response has been noted. Other agents such as histone deacetylase inhibitors and peroxisome proliferator-activated receptor-γ agonists are being studied. These patients require very close follow-up. Thyroglobulin levels, radioactive iodine scanning, and PET scans should be included in the algorithm for long-term follow-up of patients with locally advanced thyroid carcinoma [1].

In the literature, patients with isolated local and nodal recurrence after conservative treatment were treated with salvage therapy consisting of radical resection, lymph node dissection, and radioactive iodine ablation. Anaplastic transformation was encountered in 14% with a history of incomplete resection in one series [9]. Five-year disease free survival was accomplished in all patients [21] and 100% survival rate in a series of patients younger than 45 years [9]. All patients who didn’t survive in our series were >45 years old. Also of note is that Ballantyne [27], in reviewing the MD Anderson experience, despite the majority of patients having undergone prior treatment, 5-year survival was >50% overall and was noted to be >70% for patients with papillary or follicular carcinomas.

The current series has several limitations. The small number of patients is to be considered when interpreting the results, mainly leading on to underpower the statistical tests and inflate the type II error. The retrospective collect of data is another shortcoming. Selection biases are also inherent to this study, since the patients were selected from the database of tertiary university hospital. Since it is a retrospective series, a different prospective study is needed to evaluate the diagnostic significant of MRI and CT scan in the management of locally advanced thyroid carcinoma.

CONCLUSIONS

On the basis of our results, we believe that age and histologic type are important in determining the prognosis of locally invading thyroid cancer. Thyroidectomy associated with resection of a major portion of the adjacent structures are compatible with life without guarantying high survival rates.
